Key words:
Length of femur Head of femur, Femoral condyle, Medico Legal Investigations.

ABSTRACT

Topic: Determination of sex by using the length of femur in Tamilnadu.
Aim: To do the study of determination of sex using dry femur bones.
Objective: To find the gender by identifying the length of femur bone.
Background: Identification of sex from skeleton is an important demographic assessment in medico legal investigations. Length of femur is an important and reliable skeletal element for sex determination. The present study aims at obtaining results from the length of femur. The length of femur which is taken as the maximum vertical distance between the upper end of head of femur and lowest point on femoral Condyle.
Reason: This will be helpful in solving forensic problem to some extent.

INTRODUCTION

The femur is the only bone located within the human thigh. It is both the longest and the strongest bone in the human body, extending from the hip to the knee. The femur is the longest and, by most measures, the strongest bone in the human body. Its length on average is 26.74% of a person's height a ratio found in both men and women and most ethnic groups with only restricted variation, [2] and is useful in anthropology because it offers a basis for a reasonable estimate of a subject's height from an incomplete skeleton. [1] Sex determination of the unknown skeletal material is one of the most vital questions required to be answered with 100% accuracy in [3] medico legal cases as a part of establishing identity of the diseased from skeletal remains. Therefore in the present study femur bones were studied for the determination of sex in the populations of South India.

MATERIALS AND METHOD

The present study was Carried out Using 30 dry femur bones of the adult males and females from the department of anatomy Saveetha Dental College. An Inch tape was utilized to measure maximum length of femur which is taken as the maximum vertical distance between the upper end of head of femur and lowest point on femoral Condyle.

RESULT

The values of the mean maximum length in male femora in south India was 44.25 (right) and 43.35 (left) and that in female 41.8 mm (right) and 42.25 mm (left). The mean values obtained were in accordance with that of the values calculated from various other researchers which can be seen in the tables A and B given below.
Determination of sex by using the length of adult femur bones

**CONCLUSION**

To conclude the result of the present study further confirms the views of earlier workers that population specific studies in this aspect are mandatory and beneficial for sex determination. The results of the present study will help in accurate diagnosis of sex from both complete and fragmentary femora from South Indian population and thus constitutes an important tool for forensic experts.

**DISCUSSIONS**

Sex determination from long bones or their fragments is required as it is a possible identity. The [5] forensic experts often face problems with poorly preserved or fragmented bones which makes their identification complicated [4] due to the tubular structure of the bones they are preserved better than the normal bones. Thus the data collected from the femur bones was beneficial. In the past [8] the percentage accuracy of males was less compared to that of the females it the specificity was higher in case of males; this could be due to the more [9] variable lifestyle and the difference in the labour of both these sexes [10] which can be a determining factor of the length of the femur bones.

**Statistical for maximum femoral length**

### Table A: Comparison of Maximum femoral length in MALES

<table>

</table>

[7] However the effect of the environment and the genetical factors are also to be considered. Although all the measurements were more in Males as compared to that of the females in conclusion of the present study fulfils the need to update Standards that can be used in determining sex in the identification process.
